In today’s presentation we will cover information regarding the organism that causes canine influenza and its epidemiology. We will also talk about the history of the disease, how it is transmitted, species that it affects (including humans), and clinical and necropsy signs observed. Finally, we will address prevention and control measures, as well as actions to take if canine influenza is suspected.

The canine influenza virus is a member of the Influenzavirus A genus in the family Orthomyxoviridae. Influenza A viruses are classified into subtypes based on two surface antigens, the hemagglutinin (H) and neuraminidase (N) proteins. There are 16 hemagglutinin antigens (H1 to H16) and 9 neuraminidase antigens (N1 to N9), but only limited subtypes are found in each species of mammal.

[Photo: This digitally-colorized negative-stained transmission electron micrograph (TEM) depicts a number of influenza A virions. Source: CDC Public Health Image Library]

There are many closely related influenza viruses that infect birds (avian influenza viruses), horses (equine influenza viruses), pigs (swine influenza viruses) and people (human influenza A viruses). Each of these viruses has a higher specificity for one species or related group of animals (e.g. birds). Equine influenza viruses, for example, typically infect only horses and other members of the Equidae. Occasionally, an influenza virus from one species infects a member of another species. Typically, the virus is poorly adapted to the new host and cannot be transmitted efficiently. For this reason, most of these infections remain limited to individual animals or small groups.
In some instances, influenza viruses have been able to jump from one species to another. Although permanent adaptation to another species is uncommon, it is aided by two characteristics of influenza viruses: their high mutation rate and their ability to recombine with each other.

H3N8 viruses are currently the predominant subtype in horses. The canine influenza virus, which also has the subtype H3N8, appears to have jumped directly from horses to dogs. This virus is considered to be a canine influenza virus because it has acquired the ability to spread from dog to dog. An analysis of the H3N8 canine influenza virus has demonstrated that it is most closely related to the H3N8 ‘Florida lineage’ equine influenza virus that emerged in the early 1990s. There are four amino acid differences between the hemagglutinin proteins in the equine and canine viruses; these changes were probably important in adapting the virus to dogs. The evidence suggests that a single virus was transmitted whole from horses to dogs, as a one-time event. Recent studies show that the canine H3N8 influenza virus has now diverged considerably from the H3N8 equine influenza virus from which it originated, and appears to belong to a separate lineage.

A second subtype, an H3N2 virus isolated in Korea, has the potential to become a second canine influenza virus. There is evidence that this virus may have been transmitted between dogs during an outbreak, and dog-to-dog transmission is reported to occur readily in experimentally infected dogs. At least three different isolates of this virus have been recovered. Unlike the H3N8 virus, the H3N2 virus seems to have originated in birds. The H3N2 viruses are reported to contain gene segments which may come from several different avian viruses. The source of the H3N2 virus is not known, but one possibility is that it originated in uncooked poultry products fed to dogs. One dog might also have been exposed at a poultry market. There have been sporadic reports of other influenza viruses, including the high pathogenicity avian H5N1 virus, in dogs. However, these viruses have not been readily transmitted between dogs. For this reason, they are not considered to be canine influenza viruses.
Canine influenza was first reported in racing greyhounds, and initially seemed to be confined to this breed. Beginning in 2004, outbreaks of respiratory disease occurred at greyhound kennels and racetracks in a number of U.S. states. The canine influenza virus was found to be responsible for some outbreaks, and is thought to have been involved in others. Serologic evidence suggests that this virus has been circulating among greyhounds since at least 1999. Recently, it has also caused respiratory disease in a variety of breeds in the general canine population. All dogs regardless of breed are now considered to be susceptible. [Photo: Greyhounds racing. In the U.K., an H3N8 virus was responsible for an independent outbreak of respiratory disease in a foxhound kennel in 2002. Limited serologic evidence also suggests that some foxhounds were exposed to an H3N8 virus in 2003. These cases were caused by equine H3N8 viruses that apparently did not become established in the canine population. In 2007, a different influenza virus caused an outbreak of canine respiratory disease in Korea. This virus appears to be entirely of avian origin (H3N2), but can be transmitted between dogs. As of 2009, it has been reported only from a limited geographic area.

In 2004-2006, infections occurred in racing greyhounds in a number of states including Florida, Texas, Arkansas, Alabama, Arizona, West Virginia, Kansas, Iowa, Colorado, Rhode Island and Massachusetts. Infected pet dogs were first reported in Florida, but the H3N8 virus has since spread to other areas. This virus seems to spread unpredictably. It has apparently become established in some regions including Colorado, Florida and the New York City area (New York, New Jersey and Connecticut), but its persistence in other areas is uncertain. Although infected dogs have also been reported from several other states, the virus seems to have disappeared from some.
Since the first reported case of canine influenza was reported in Florida in 2004, the disease has spread and been confirmed in 40 states.

The prevalence of this disease in the U.S. is not yet known. Because dogs have not been exposed to the canine influenza virus before, most of the population is expected to be fully susceptible. Many cases have been linked to shelters, boarding kennels and other areas where dogs are in close proximity. In kennels, the infection rate may reach 100% and clinical signs often occur in 60-80% of the dogs infected. Most dogs are expected to develop the less severe form of the disease and recover; however, a more severe form with pneumonia occurs in a minority. Deaths typically occur in dogs with severe disease; the mortality rate is thought to be 1-5%, although some sources suggest that it may be as high as 8%. Secondary bacterial infections appear to contribute significantly to these deaths. Higher case fatality rates have been reported in small groups of greyhounds. At one Florida greyhound racetrack, the case fatality rate was 36%. High case fatality rates are not expected in most canine populations; however, severe disease is more likely in dogs that are in poor condition or are concurrently exposed to other pathogens.

The H3N2 virus has been reported only from an outbreak at three veterinary hospitals and a kennel in South Korea. Cases were described in a miniature schnauzer, a cocker spaniel, a Yorkshire terrier and two Jindo dogs (a Korean breed of hunting dog), as well as 13 dogs of unknown breeds at an animal shelter. This disease appears to be relatively severe: only one of the five dogs seen at veterinary clinics survived. The fate of the dogs in the animal shelter was not stated.
In mammals, influenza viruses are usually transmitted in aerosols created by coughing and sneezing, and by contact with nasal discharges, either directly or on fomites. Close contact and closed environments favor transmission. Influenza viruses are relatively labile, but can persist for several hours in dried mucus. Transmission of the canine influenza viruses between dogs appears to be similar. Both the H3N8 and H3N2 viruses are found in respiratory secretions; neither virus has been reported in feces. Dogs can shed the H3N8 virus for seven to 10 days after the onset of clinical signs. Approximately 20-25% of dogs remain asymptomatic; however, these dogs can also shed the virus. Dogs that were experimentally infected with H3N2 viruses shed these viruses in nasal secretions from the second to sixth day after inoculation.

There are no reports of human infections with canine influenza viruses, and no evidence that any species other than dogs can be infected. However, it may be theoretically possible for dogs to become a source of novel influenza virus transmission to humans. As a precaution, physicians, veterinarians and others have been asked to report any cases of human influenza that seem to be linked to exposure to canine influenza. As a general practice, it is prudent for immunocompromised people, the elderly, young children and pregnant women to avoid contact with animals that are ill.

**Species Affected**
- Reported only in dogs
- All breeds susceptible
  - No known breed predilection

**Disease in Dogs**
- Incubation period: 2-5 days
- Clinical signs
  - Mild respiratory disease
  - Persistent cough
  - Purulent nasal discharge
  - Lethargy, anorexia
  - Fever
- Severe form exists

The incubation period for H3N8 canine influenza is approximately 2 to 5 days; most cases appear in 2 to 3 days. The most common presentation seen with H3N8 viruses is a mild respiratory disease that resembles infectious tracheobronchitis (kennel cough). In this form, an initial (usually low grade) fever is followed by a persistent cough and sometimes a purulent nasal discharge. The cough may be either soft and moist, or dry, and can last for up to 3 to 4 weeks regardless of treatment. The purulent nasal discharge appears to resolve with antibiotics, suggesting that secondary bacterial infections may be important in this disease. Lethargy and anorexia are common. More severely affected dogs exhibit a high fever with an increased respiratory rate and other signs of pneumonia or bronchopneumonia. Asymptomatic seroconversion also occurs. The only known outbreak of H3N2 canine influenza was characterized by severe respiratory disease with fever, nasal discharge, sneezing, coughing and anorexia.

**Post Mortem Lesions**
- Gross lesions
  - Hemorrhages
    - Lungs, mediastinum, pleural cavity
    - Fibrinous pleuritis
- Histology
  - Tracheitis
  - Bronchitis
  - Bronchiolitis
  - Pneumonia

In fatal cases of H3N8 virus infection, hemorrhages may be found in the lungs, mediastinum and pleural cavity. The lungs may exhibit signs of severe pneumonia, and can be dark red to black. Fibrinous pleuritis can also be seen in some cases. On histologic examination, there may be tracheitis, bronchitis, bronchiolitis, and severe interstitial or bronchointerstitial pneumonia. There is limited information on the lesions found in mild cases.

**Clinical Diagnosis**
- Suspect canine influenza in dogs with persistent cough, pneumonia, or other respiratory signs
- Differential diagnosis
  - Other respiratory diseases
  - Kennel cough

Canine influenza should be suspected in dogs with a persistent cough; this disease often resembles infectious tracheobronchitis (kennel cough). In a kennel or other facility, the occurrence of clinical signs in many dogs is suggestive. Canine influenza is also a consideration in dogs with pneumonia and other, more severe respiratory signs. The differential diagnosis includes other respiratory diseases, particularly kennel cough.
# Canine Influenza

## Laboratory Diagnosis
- **Serology**
  - Hemagglutination inhibition
  - Virus neutralization
- **Antigen detection**
  - RT-PCR
  - Virus isolation
  - Antigen-capture ELISA

Hemagglutination inhibition is the most commonly used serologic test. Virus neutralization (microneutralization test) can also be done, but this test is usually too cumbersome for routine use. Antibodies may be present as soon as 6 to 8 days after the onset of disease. RT-PCR is the most reliable method to detect the virus directly. This test can be used in live animals (swabs) or at necropsy. Virus isolation may also be successful in some dogs, during the early stages of disease before antibodies develop. H3N8 canine influenza virus has been isolated in both embryonated eggs and cell cultures (MDCK cells); some viruses have been recovered in only eggs or cells, while others can be isolated in both systems. Virus isolation may fail to detect the virus in many infected dogs that do not die of the disease. Nevertheless, it is important to track genetic changes in this virus as it spreads in canine populations. For this reason, some laboratories may conduct virus isolation, at no cost, on samples positive by PCR. Antigen-capture ELISA tests do not seem to be reliable in individual dogs, probably because the amount of virus shed is low. However, these tests may be able to detect H3N8 canine influenza during outbreaks at kennels or other large facilities.

## Treatment
- **Antibiotics**
  - Secondary bacterial infections
- **Supportive care**
  - Hydration

Antibiotics appear to be important in the treatment of H3N8 canine influenza, which seems to be complicated by secondary bacterial infections in some cases. Broad-spectrum antibiotics are used in the severe form of disease. These antibiotics are also used to control the signs of secondary bacterial infections (e.g. a purulent nasal discharge) in the milder form. Supportive treatment including hydration is also important.

## Prevention and Control
- **Vaccination**
- **Infection control in kennels**
  - Cleaning and disinfection
  - Hand washing
  - Isolation

A conditionally licensed vaccine for dogs has been released in the U.S. Vaccines for other respiratory diseases such as kennel cough, may help control pathogens that could become secondary invaders. Influenza viruses usually spread most readily when animals are gathered together. Good infection control practices will help protect dogs in kennels, boarding facilities, dog shows and similar situations. Cages, bowls and other fomites should be cleaned and disinfected between uses. Workers should wash their hands with soap and water after handling dogs or cleaning cages, and after contact with saliva, urine, feces or blood, as well as after entering or before leaving the facility. Clothing can be cleaned by washing it with detergent at normal laundry temperatures. Isolation protocols, including the use of disposable gloves, should be used for any dog that develops respiratory signs.

Canine Influenza

Prevention and Control

- Veterinarians
  - Be aware of outbreaks
  - Use contagious disease protocols
- Isolate infected dogs
- Use good hygiene
- Clean and disinfect facilities after outbreak

Veterinarians should be alert to announcements of canine influenza outbreaks in an area. Clients should also be advised to consult a veterinarian if their dog develops signs of a respiratory illness, and should be questioned about potential exposures to other dogs such as recent boarding. Veterinarians should use contagious disease protocols for all dogs with respiratory symptoms. This includes the isolation of infected dogs during diagnosis and treatment, and during hospitalization if it becomes necessary. It should be kept in mind that asymptomatically infected dogs are also expected to be contagious. If an outbreak occurs at an establishment, a quarantine and the isolation of infected animals would reduce virus dissemination to the community and within the facility. Good hygiene can help prevent influenza viruses from spreading on fomites. Infected facilities should be cleaned and disinfected after the outbreak.

Disinfection

- 1% sodium hypochlorite
- Quaternary ammonium compounds
- 70% ethanol
- Glutaraldehyde, formaldehyde
- Lipid solvents
- Heat (56°C/133°F) for 30 minutes
- Radiation
- Low pH (pH 2)

Influenza viruses, including canine influenza viruses, are readily killed by commonly used disinfectants. In general, influenza viruses are susceptible to a variety of disinfectants including 1% sodium hypochlorite, quaternary ammonium compounds, 70% ethanol, glutaraldehyde, formaldehyde and lipid solvents. They can also be inactivated by heat of 56°C (133°F) for a minimum of 30 minutes, as well as by radiation or low pH (pH 2).
