Avian Influenza
Fowl Plague, Grippe Aviaire

Importance
Avian influenza viruses are highly contagious, extremely variable viruses that are widespread in birds. Wild birds in aquatic habitats, particularly waterfowl and shorebirds, are thought to be their natural reservoir hosts, but domesticated poultry can also be infected. Most of these viruses cause only mild disease in poultry, and are called low pathogenic avian influenza (LPAI) viruses. Highly pathogenic avian influenza (HPAI) viruses can develop from certain LPAI viruses, usually while they are circulating in poultry flocks. HPAI viruses can kill up to 90-100% of the flock, and cause epidemics that may spread rapidly, devastate the poultry industry and result in severe trade restrictions. In poultry, the presence of LPAI viruses capable of evolving into HPAI viruses can also affect international trade.

Avian influenza viruses can occasionally affect mammals, including humans, usually after close contact with infected poultry. While infections in people are often limited to conjunctivitis or mild respiratory disease, some viruses can cause severe illness. In particular, Asian lineage H5N1 HPAI viruses have caused rare but life-threatening infections, now totaling more than 650 laboratory-confirmed cases since 1997, while more than 400 serious illnesses were caused by an H7N9 LPAI virus in China during 2013-2014 alone. H5N1 HPAI viruses can also infect other species of mammals, in some cases fatally. In rare cases, avian influenza viruses can become adapted to circulate in a mammalian species, and these viruses have caused or contributed to at least three past pandemics in humans.

Etiology
Avian influenza results from infection by viruses belonging to the species *influenza A virus*, genus *influenzavirus A* and family *Orthomyxoviridae*. These viruses are also called type A influenza viruses. Influenza A viruses are classified into subtypes based on two surface proteins, the hemagglutinin (HA) and neuraminidase (NA). A virus that has a type 1 HA and type 2 NA, for example, would have the subtype H1N2. At least 16 hemagglutinins (H1 to H16), and 9 neuraminidases (N1 to N9) have been found in viruses from birds, while two additional HA and NA types have been identified, to date, only in bats. Some hemagglutinins, such as H14 and H15, seem to be uncommon, or perhaps are maintained in wild bird species or locations that are not usually sampled.

Avian influenza viruses are classified as either low pathogenic (also called low pathogenicity) avian influenza viruses or highly pathogenic (high pathogenicity) avian influenza viruses. A virus is defined as HPAI or LPAI by its ability to cause severe disease in intravenously inoculated young chickens in the laboratory, or by its possession of certain genetic features that have been associated with high virulence in HPAI viruses (i.e., the sequence at the HA cleavage site). HPAI viruses usually cause severe disease in chicken and turkey flocks, while LPAI infections are generally much milder in all avian species. With rare exceptions, HPAI viruses found in nature have always contained the H5 or H7 hemagglutinin. Two exceptions were H10 viruses that technically fit the HPAI definition if they were injected directly into the bloodstream of chickens, but caused only mild illness in birds that became infected by the respiratory (intranasal) route. Another H10 virus also fit the HPAI definition; however, this virus affected the kidneys and had a high mortality rate in intranasally inoculated young chickens. Non-H7, non-H5 viruses that are pathogenic only after intravenous inoculation have been created in the laboratory by inserting genetic sequences from HPAI viruses. However, some viruses created this way (containing H2, H4, H8 or H14) were highly virulent after both intravenous and intranasal inoculation. Whether such viruses could evolve naturally from LPAI viruses is still uncertain.

In rare cases, an H5 or H7 virus has a genetic signature that classifies it as an HPAI virus, but causes only mild illness in poultry. Such viruses may have been isolated when they were evolving to become more virulent. Their presence triggers the same regulatory responses as fully virulent HPAI viruses.
Antigenic shift and drift in influenza A viruses

The viral HA, and to a lesser extent the NA, are major targets for the immune response, and there is ordinarily little or no cross-protection between different HA or NA types. Influenza A viruses are very diverse, and two viruses that share a subtype may be only distantly related. The high variability is the result of two processes, mutation and genetic reassortment. Mutations cause gradual changes in the HA and NA proteins of the virus, a process called ‘antigenic drift.’ Once these proteins have changed enough, immune responses against the former HA and NA may no longer be protective.

Genetic reassortment can cause more rapid changes. The influenza A genome consists of 8 individual gene segments, and when two different viruses infect the same cell, gene segments from both viruses may be packaged into a single, novel virion. This can occur whenever two influenza viruses replicate in the same cell, whether the viruses are adapted to the same host species (e.g., two different avian influenza viruses) or originally came from different hosts (for instance, an avian influenza virus and a swine influenza virus). An important aspect of reassortment is that it can generate viruses containing either a new HA, a new NA, or both. Such abrupt changes, called ‘antigenic shifts,’ may be sufficient for the novel virus to completely evade existing immunity. After a subtype has become established in a species and has circulated for a time, antigenic shifts and drift can produce numerous viral variants.

Avian influenza virus lineages

There are two well-recognized lineages of avian influenza viruses, Eurasian and North American. As implied by the names, Eurasian lineage viruses primarily circulate among birds in Eurasia, and North American lineage viruses in the Americas. The amount of reassortment between these lineages seems to differ between regions, with very few reassortant viruses in some areas or wild bird populations, but significant reassortment where there is overlap between migratory flyways, such as in Alaska and Iceland. Viruses in wild birds (or portions of viruses) are more likely to be transferred between regions where there is high reassortment. Avian influenza virus surveillance in Central and South America has been limited, but the viruses detected include a unique South American subtype (or lineage) as well as viruses closely related to the North American lineage. An analysis of a limited number of H7 avian influenza viruses suggests that the viruses in New Zealand and Australia might be geographically isolated.

Transfer of influenza viruses between species

Although influenza A viruses are adapted to circulate in a particular host or hosts, they can occasionally infect other species. In most cases, the virus cannot be transmitted efficiently between members of that species, and soon disappears. On rare occasions, however, a virus continues to circulate in the new host, either “whole” or after reassorting with another influenza virus. Some influenza A viruses have become adapted to circulate in pigs (swine influenza viruses), horses (equine influenza viruses), humans (human influenza A viruses) and dogs (canine influenza viruses). The ancestors of these viruses are thought to have originated in birds, either in the distant past or more recently. Further information about virus transmission between species can be found in the ‘Influenza’ factsheet.

Species Affected

Wild birds

The vast majority of LPAI viruses are maintained in asymptomatic wild birds, particularly birds in wetlands and other aquatic habitats, which are thought to be their natural reservoir hosts. Some species may maintain viruses long-term, while others might be spillover hosts. Infections are particularly common among members of the order Anseriformes (waterfowl, such as ducks, geese and swans) and two families within the order Charadriiformes, the Laridae (gulls and terns) and Scolopacidae (shorebirds). However, infections may be uncommon in some members of these orders. Within the Laridae, viruses tend to occur more often in gulls than terns. Aquatic species belonging to other orders occasionally have high infection rates, and might also be involved in the epidemiology of this disease. For instance, infections among seabirds seem to be particularly common in murres (Uria spp.).

The most common influenza subtypes in wild birds may differ between species and regions, and can change over time. Migrating birds, which can fly long distances, may exchange viruses with other populations at staging, stopover or wintering sites. Virus diversity seems to be particularly high among charadriiform birds. A few avian influenza subtypes seem to have a limited host range. Examples include H13 viruses, which occur mainly in gulls and terns, and H14 viruses, which have been detected rarely and only in a few species. Such viruses may rarely (or never) be transferred to poultry.

HPAI viruses can also infect wild birds that live on land (terrestrial birds), such as raptors and passerines, but under ordinary conditions, infections seem to be uncommon in these species, and they are not thought to be important reservoirs. Higher infection rates are occasionally reported in individual species, and in a study from Vietnam, viruses were particularly common in some terrestrial birds that forage in flocks, with an especially high prevalence in Japanese White-eyes (Zosterops japonicus). HPAI viruses are not usually found in wild birds, although they may be isolated transiently near outbreaks in poultry. Exceptions include the Asian lineage H5N1.
Avian Influenza

viruses, which have been found repeatedly in wild birds, an H5N3 virus isolated from an outbreak among terns in the 1960s, an H7N1 virus that was isolated from a sick wild siskin, Carduelis spinus, and an H5N2 virus found in a few asymptomatic wild ducks and geese in Africa.\textsuperscript{26,31,92,120-136}

\textbf{Domesticated birds and mammals}

When LPAI viruses from wild birds are transferred to poultry, the viruses may circulate inefficiently and die out; become adapted to the new host and continue to circulate as LPAI viruses; or if they contain H5 or H7, they may evolve into HPAI viruses.\textsuperscript{4,10,12} Once a virus has adapted to poultry, it rarely re-establishes itself in wild birds.\textsuperscript{10} HPAI and LPAI viruses have been found in many domesticated birds, including gallinaceous poultry and game birds, ducks, geese, raptors, pigeons and cage birds; however, some species seem to be more resistant to infection and/or illness than others.\textsuperscript{2,26,61,126,127,129-131,137-162} For example, there are few reports of infections in psittacine birds, and pigeons appear to be relatively resistant to infection compared to poultry.

Mammals that have been infected occasionally by avian influenza viruses include cats, dogs, pigs, horses, donkeys, mink, and various wild and captive wild mammals.\textsuperscript{12,19-34,82,163-176} Ferrets can be infected experimentally with many viruses.

\textbf{Important viral lineages and susceptible species}

Poultry can be infected by many different LPAI and HPAI viruses, belonging to multiple subtypes, but three viral lineages are currently of particular concern. Some of these viruses have also been reported in mammals.

\textbf{Host range of the Asian lineage H5N1 avian influenza viruses and reassortants}

The A\textsuperscript{g}oose/Guangdong/1996 lineage ("Asian lineage") of H5N1 HPAI viruses first emerged among poultry in China in the late 1990s, and has become widespread and very diverse.\textsuperscript{12,177-187} Some variants differ in their virulence for mammals and/or birds.\textsuperscript{130,182,184}

Asian lineage H5N1 HPAI viruses seem to have an unusually wide host range. These viruses can infect a wide variety of wild birds belonging to many different orders, including the Anseriformes and Charadriiformes.\textsuperscript{26,31,92,123-136} Both clinical cases and asymptomatic infections have been described.\textsuperscript{26,132,135,185} Whether wild birds can maintain these viruses for long periods (or indefinitely), or are repeatedly infected from poultry, is still controversial.\textsuperscript{123,128,135,186-188} Asian lineage H5N1 viruses can also infect many species of mammals, and their full host range is probably not yet known. They have been found in pigs, cats, dogs, donkeys, tigers (Panthera tigris), leopards (Panthera pardus), clouded leopards (Neofelis nebulos), lions (Panthera leo), Asiatic golden cats (Catopuma temminckii), stone martens (Mustela foina), raccoon dogs (Nyctereutes procyonoides), palm civets (Chrotogale owstoni), plateau pikas (Ochotona curzoniae) and a wild mink (Mustela vison).\textsuperscript{12,16,35} Serological evidence of infection or exposure has also been reported in horses and raccoons.\textsuperscript{19,189-191} Experimental infections have been established in cats, dogs, foxes, pigs, ferrets, laboratory rodents, cynomolgus macaques (Macaca fascicularis) and rabbits.\textsuperscript{16,26,30,33,92,131,184,192-201} Cattle could be experimentally infected with viruses isolated from cats,\textsuperscript{200} but studies in Egypt detected no antibodies to H5N1 viruses in cattle, buffalo, sheep or goats, suggesting that these species are not normally infected.\textsuperscript{189}

HPAI H5N2, H5N5 and H5N8 viruses, resulting from reassortment between the Asian lineage H5N1 viruses and other avian influenza viruses (including H9N2 viruses, see below), have been reported among poultry in Asia and H5N5 viruses have been found repeatedly in China. One H5N8 reassortant has recently emerged to cause widespread outbreaks in parts of Asia and Europe.\textsuperscript{202-207} Some of these viruses, such as an H5N2 virus isolated recently from a dog with respiratory signs, may be able to cause illness in mammals.\textsuperscript{163,208,209} This H5N2 virus could be transmitted from experimentally infected dogs to dogs, chickens and cats.\textsuperscript{163,208,209}

\textbf{Host range of H9N2 (LPAI) avian influenza viruses}

H9N2 (LPAI) viruses, which are currently widespread among poultry in some areas, have become very diverse, and numerous reassortants, including some that share internal genes with H5N1 viruses, have been reported.\textsuperscript{168,210-216} H9N2 viruses have been detected in wild birds.\textsuperscript{214,215}

H9N2 viruses have been found occasionally in pigs, and might sometimes cause clinical signs in this species.\textsuperscript{166,169,216} They have also been found in dogs,\textsuperscript{14,170} and infections can be reproduced experimentally in this species.\textsuperscript{217} Serological evidence of infection was detected in performing macaques in Bangladesh, and in wild plateau pikas in China.\textsuperscript{176,218} Pikas could be infected experimentally.\textsuperscript{176} H9N2 variants may differ in their ability to replicate in mammals and/or cause disease.\textsuperscript{212,213}

\textbf{Host range of the zoonotic H7N9 avian influenza viruses}

An H7N9 LPAI virus, which has recently caused serious human outbreaks in China, circulates there in poultry.\textsuperscript{14,15,219-223} This virus acquired some of its genes from H9N2 viruses.\textsuperscript{220,224}

Among birds, infections have mainly been found in poultry (and in environmental samples from poultry markets, farms and similar sites), although this virus or its nucleic acids were also detected in two pigeons, an asymptomatic tree sparrow, and wild waterfowl.\textsuperscript{223,225,226} Whether wild birds play any role in spreading this virus is uncertain.\textsuperscript{223,226,227} Experimental infections have been established in Japanese quail (Coturnix coturnix japonica), several species of ducks, Embden geese, pigeons, zebra finches (Taeniopygia guttata), society finches (Lonchura striata domestica), house sparrows (Passer domesticus) and parakeets (Melopsittacus undulates), but pigeons and Pekin ducks required high doses to become infected, and only chickens and quail transmitted this virus efficiently to other
birds.\textsuperscript{228,229} Nevertheless, some of these birds (including passerine birds and parakeets), shed high titers in oropharyngeal secretions, and may be capable of infecting humans.\textsuperscript{229}

There have been no reports of illnesses in mammals, as of September 2014, and no evidence of H7N9 infections was found among stray dogs living near live poultry markets.\textsuperscript{24} In experimental studies, isolates from humans can infect miniature pigs, ferrets, laboratory mice and cynomolgus macaques.\textsuperscript{230-232} At present, there have been no reports of infected pigs in China.\textsuperscript{223}

H7N7 LPAI viruses that resemble these H7N9 viruses in some of their genes have also been identified among poultry in China, and might have the potential to infect mammals.\textsuperscript{224}

Other avian influenza viruses reported in mammals

Infections caused by other avian influenza viruses are reported sporadically in mammals. In addition to H5N1 and H9N2 viruses, diverse subtypes (e.g., H4, H5N2, H6N6, H7, H10N5 and H11N2) have been isolated occasionally from pigs, especially in Asia, and antibodies to avian H3 viruses have also been found.\textsuperscript{148,166-168,171-175,233} While many infections with avian influenza viruses are transient, some established swine influenza viruses are wholly of avian origin or contain avian-origin gene segments.\textsuperscript{37,38,47,91,106,107,216} (The Swine Influenza factsheet has additional information about these viruses.) One avian H3N8 virus affected horses in China for a short time, starting in 1989, but did not persist long term.\textsuperscript{234,235} An H10N4 virus was responsible for an epidemic in farmed mink, and experimental infections with H3N8, H4N6, H5N3, H7N7, H8N4 and H11N4 avian influenza viruses have been established in this species.\textsuperscript{1,30}

Cats have been infected experimentally with some LPAI viruses (H1N9, H6N4, and H7N3) from waterfowl, as well as with an H7N7 HPAI virus isolated from a fatal human illness,\textsuperscript{236-238} and dogs were infected with an H6N1 LPAI virus.\textsuperscript{239} Serological evidence of infection with H10N8 viruses has been reported in dogs.\textsuperscript{240} Domesticated guinea pigs in South America had antibodies to H5 influenza viruses.\textsuperscript{241} Few studies have investigated wild animals; however, antibodies to H4 and H10 viruses were found in raccoons in the U.S. (in addition to antibodies to H1 and H3 viruses, which could also originate from mammals), and antibodies to H3N8 viruses, possibly of avian origin, were reported in Japan.\textsuperscript{191,242,243} Raccoons could be infected experimentally with an avian H4N8 virus,\textsuperscript{242} and striped skunks (Mephitis mephitis) with H4N6 and H3N8 viruses.\textsuperscript{244}

Laboratory mice (Mus musculus) and ferrets serve as models for mammalian infections with influenza viruses, including avian influenza viruses.\textsuperscript{246-254} Most laboratory mice have a defective gene (Mx1), which increases their susceptibility to influenza viruses compared to their wild-type progenitors.\textsuperscript{255-257} However, one recent study suggested that wild Mus musculus mice may also be susceptible to experimental inoculation with certain LPAI viruses.\textsuperscript{255} Wild house mice (Mus musculus) at the site of an H5N8 avian influenza outbreak in poultry had serological evidence of infection with influenza A viruses (either avian or mammalian), but confirmatory testing and identification of the serotype could not be done due to the low sample volumes, and the virus could not be detected directly.\textsuperscript{255} Some other studies have found no evidence for influenza viruses in wild mice.\textsuperscript{258-260}

Zoonotic potential

The two most commonly reported avian influenza viruses from human clinical cases have been the Asian lineage H5N1 HPAI viruses, and recently, H7N9 LPAI viruses in China.\textsuperscript{14,15,38,92,219-223,261} Illnesses caused by other subtypes have also been reported sporadically, with documented clinical cases caused by H9N2, H6N1 and multiple H7 and H10 avian influenza viruses.\textsuperscript{84,92,262-282} Viruses that tend to cause milder illnesses (e.g., H9N2 viruses) are less likely to be identified than those causing severe disease. Serological surveys in some highly exposed populations suggest the possibility of low level exposure to HA types found in birds, including H4, H5, H6, H7, H9, H10, H11 and H12.\textsuperscript{168,275,283-298} Human volunteers could be infected with some subtypes (e.g., H4N8, H10N7 and H6N1), and sometimes developed mild respiratory signs and other influenza symptoms.\textsuperscript{252} Adaptation to humans is possible, though rare, and some previous human pandemics were caused by partially or wholly avian viruses.\textsuperscript{1,36,38,40,41,299}

Geographic Distribution

LPAI viruses are cosmopolitan in wild birds, although the specific viruses differ between regions.\textsuperscript{1,7,80,81} These viruses are usually absent from commercial poultry in developed nations, but they may be present in other domesticated birds.\textsuperscript{3} H9N2 viruses are currently widespread among poultry in parts of Asia and the Middle East.\textsuperscript{300-303} They have been detected in wild birds in Europe, where they also caused a few outbreaks in poultry flocks, and were isolated from game birds.\textsuperscript{215,304,305} The zoonotic H7N9 LPAI viruses causing outbreaks in mainland China have not been reported from other regions, with the exception of imported cases in travelers (e.g., in Taiwan, Hong Kong and Malaysia).\textsuperscript{14,15,306,307} HPAI viruses are eradicated from all domesticated birds, whenever possible, and developed countries are usually HPAI-free. Asian lineage H5N1 HPAI viruses are currently considered to be endemic among poultry in a few nations in Asia and the Middle East, with outbreaks occurring at times in other countries in the Eastern Hemisphere.\textsuperscript{12} These viruses can also be found in wild birds in Eurasia,\textsuperscript{26,123,125-128,130,187,188,308,309} but have not been detected in the Americas, Australia or New Zealand, as of 2014.\textsuperscript{26,69,75,310,311} Worldwide eradication of this H5N1 lineage is not expected in the near future.\textsuperscript{12,312}
Transmission

Avian influenza viruses are shed in the feces and respiratory secretions of birds.1,2,6 The feces contain large amounts of virus in aquatic species such as waterfowl, and the fecal-oral route is thought to predominate in wild bird reservoirs.7,130,313,314 Fecal-cloacal transmission might also be possible.1 Respiratory transmission is thought to play little or no role in aquatic birds,7 with the exception of some isolates of Asian lineage H5N1 HPAI viruses,130,144,314 and possibly a few LPAI viruses.315 Respiratory spread might be more important in some wild terrestrial species.7,116

Once an avian influenza virus has entered a poultry flock, it can spread on the farm by both the fecal–oral route and aerosols, due to the close proximity of the birds. Fomites can be important in transmission, and flies may act as mechanical vectors.2,24,316,317 The possibility of wind-borne transmission of HPAI viruses between farms was suggested by one study,318 but has not been conclusively demonstrated. Avian influenza viruses have also been found in the yolk and albumen of eggs from chickens, turkeys and quail infected with HPAI viruses.319-325 Although infected eggs are unlikely to hatch, broken eggs could transmit the virus to other chicks in the incubator. It might be possible for LPAI viruses to be shed in eggs, but the current evidence suggests this is very rare, if it occurs at all.319,326

How long birds remain contagious differs between avian species, and with the severity of the infection (chickens and turkeys infected with HPAI viruses die very soon after infection). Most chickens usually excrete LPAI viruses for a week, and a minority of the flock for up to two weeks, but some species of birds, including waterfowl, may shed some LPAI or HPAI viruses for a few weeks.38,115,140,327-329

Transmission of avian influenza viruses to mammals

People and other mammals are usually infected with avian influenza viruses during close contact with infected birds or their tissues, although indirect contact via fomites or other means is also thought to be possible.12,15,22,24,25,28,29,32,164,193,330-340 Respiratory transmission is likely to be an important route of exposure, and the eye might also act as an entry point.231,252,254,314,342 A few H5N1 HPAI virus infections in animals, and rare cases in humans, have been linked to the ingestion of raw tissues from infected birds.21,22,24,25,28,29,32,193,333,318,339

Housecats in an animal shelter might have become infected from contaminated avian feces, ingested while grooming.164 Feeding experiments provide evidence that H5N1 viruses can enter the body by the oral route in cats, pigs, ferrets, mice, hamsters and foxes, and transmission has been confirmed in cats by direct inoculation of the virus into the gastrointestinal tract.21,29,193,195,196,338,343,344 In humans, the strongest evidence for oral transmission is that two people became infected with an Asian lineage H5N1 virus after eating uncooked duck blood.338 There are other human cases where ingestion probably occurred, but additional routes of exposure also existed.339

A ferret model suggested that some viruses might be transmitted to the fetus, when there is high viremia during systemic infections.345 Viral antigens and nucleic acids were also found in the fetus of a woman who died of an Asian lineage H5N1 infection.346 Transplacental transmission seems much less likely with influenza viruses that replicate only in the respiratory tract.

Host-to-host transmission of avian influenza viruses in mammals

Infected animals and people shed avian influenza viruses in respiratory secretions. Fecal shedding has been reported occasionally, although its significance is still uncertain.347,348 Some avian influenza viruses that have been detected in feces include Asian lineage H5N1 HPAI viruses in humans and experimentally infected cats and foxes; H7N9 viruses in humans; and H9N2 viruses in experimentally infected dogs.28,195,199,217,349-352 Most studies used PCR, and the presence of live influenza virus in feces was confirmed by virus isolation in only rare instances. The source of these viruses is still uncertain, and could be swallowed respiratory fluids, but Asian lineage HPAI H5N1 viruses seem to be able to replicate in human intestinal tissues.353 There are also reports of Asian lineage H5N1 HPAI viruses in the urine of some mammals.30

Sustained transmission of avian influenza viruses is a rare event in mammals, but limited host-to-host transmission has caused clusters of infections or outbreaks in animals (e.g., in mink and horses).1,30,166-168,173,271,354,355 While most infected people do not seem to transmit avian viruses to others, including family members,262-264,267 Asian lineage H5N1 HPAI viruses are capable of person-to-person transmission in rare instances,334-337 and one H7N9 HPAI virus was found in a few family members of poultry workers in the Netherlands.267,356 Likewise, the H7N9 virus in China does not appear to spread readily between people, but human-to-human transmission was suspected in a few family clusters.15,306,331,332,357-361 Close, unprotected contact, seems to be necessary to transmit any of these viruses.334-337,360,361 Sometimes person-to-person transmission can be difficult to distinguish from exposure to a common source of the virus (e.g., on fomites).

Animal-to-animal transmission of Asian lineage H5N1 HPAI viruses was reported among tigers in one outbreak at a zoo, and experimentally between cats.25,193 Experimentally infected, sick cats shed these viruses by the third day post-inoculation.193,195 However, asymptomatic, naturally infected cats appeared to excrete them only sporadically, and there was no evidence for animal-to-animal transmission.164 In one study, there was no evidence for H5N1 virus transmission between small numbers of experimentally infected dogs and cats.197 One experiment indicated that these viruses are not transmitted between pigs;16 however, studies from Indonesia suggest that limited
pig-to-pig transmission occurs within infected herds. Some authors have speculated about the possibility of virus transmission between mammals and birds in some ecosystems, based on evidence from Qinghai Lake, China, where H5N1 viruses related to those previously found in wild plateau pikas were isolated from dead migratory birds in 2009-2010, although this clade had not been found in wild aquatic birds at this location in 2007. However, there was no serological evidence of exposure to H5 viruses in a recent study of plateau pikas in this area, despite evidence of exposure to H9 viruses.

Survival of influenza viruses in the environment

Fecal-oral transmission of avian influenza viruses in birds may be facilitated by prolonged survival in some environments. The persistence of these viruses can be influenced by many factors such as the initial amount of virus; temperature and exposure to sunlight; the presence of organic material; pH and salinity (viruses in water); the relative humidity (on solid surfaces or in feces); and in some studies, by the viral strain. Avian influenza viruses survive best in the environment at low temperatures, and some studies suggest that they are more persistent in fresh or brackish water than salt water. Some viruses may survive for several weeks to several months or more in distilled water or sterilized environmental water, especially under cold conditions. However, the presence of natural microbial flora may considerably reduce their survival in water, and at some temperatures, viruses may remain viable for only a few days (or less, in some environments) to a few weeks. Other physical, chemical or biological factors in natural aquatic environments may also influence persistence. Freeze-thaw cycles might help inactivate influenza viruses in cold climates.

In feces, some anecdotal field observations stated that LPAI viruses can survive for at least 44 or 105 days, but the conditions were not specified. Under controlled laboratory conditions, LPAI or HPAI virus persistence in feces ranged from < 1 day to 7 days at temperatures of 15-35°C (59-95°F), depending on the moisture content of the feces, protection from sunlight and other factors. At 4°C (39°F), some viruses survived for at least 30-40 days in two studies, but they remained viable for times ranging from less than 4 days to 13 days in two recent reports. On various solid surfaces and protected from sunlight, viruses were reported to persist for at least 20 days and up to 32 days at 15-30°C (59-86°F), and for at least 2 weeks at 4°C if the relative humidity was low; but also for less than 2 days on porous surfaces (fabric or egg trays) or less than 6 days on nonporous surfaces at room temperature. Survival was longer on feathers than other objects in two reports: at least 6 days at room temperature in one study, and 15 days at 20°C (68°F) and 160 days at 4°C in another report. Some viruses persisted for up to 13 days in soil (4°C), for more than 50 days (20°C) or 6 months (4°C) in poultry meat (pH 7), and for 15 days in allantoic fluid held at 37°C (99°F). Exposure to direct sunlight greatly reduced virus survival. Environmental sampling in Cambodia suggested that their persistence in tropical environments might be brief: although RNA from Asian lineage H5N1 HPAI viruses was found in many samples including dust, mud, soil, straw and water, virus isolation was only successful from one water puddle.

Disinfection

Influenza A viruses are susceptible to a wide variety of disinfectants including sodium hypochlorite, 60% to 95% ethanol, quaternary ammonium compounds, aldehydes (glutaraldehyde, formaldehyde), phenols, acids, povidone-iodine and other agents. Influenza A viruses can also be inactivated by heat of 56-60°C (133-140°F) for a minimum of 60 minutes (or higher temperatures for shorter periods), as well as by ionizing radiation or extremes of pH (pH 1-3 or pH 10-14).

Infections in Animals

Incubation Period

The incubation period in poultry can be a few hours to a few days in individual birds, and up to 2 weeks in the flock. A 21-day incubation period, which takes into account the transmission dynamics of the virus, is used for an avian population in the context of disease control. The incubation period for avian influenza viruses in mammals is also thought to be short, and might be as little as 1-2 days in some cases.

Clinical Signs

Low pathogenic avian influenza

LPAI viruses usually cause subclinical infections or mild illnesses in poultry and other birds. Decreased egg production, misshapen eggs, decreased fertility or hatchability of the eggs, respiratory signs (sneezing, coughing, ocular and nasal discharge, swollen infraorbital sinuses), lethargy, decreased feed and water consumption, or somewhat increased flock mortality rates may be seen in chickens and turkeys. Illnesses exacerbated by factors such as concurrent infections or young age can be more severe. Viruses with higher virulence might also exist. One unusual H10 virus isolated from waterfowl affected the kidneys and had a 50% mortality rate in some intranasally inoculated chickens. Some gallinaceous game birds (e.g., quail, pheasants, guinea fowl, partridges) infected with LPAI viruses have been asymptomatic, while others had clinical signs including lethargy, respiratory signs such as sinusitis, conjunctivitis, decreased egg production and diarrhea. One study reported neurological signs and elevated mortality in guinea fowl (Numida meleagris) infected with...
an H7N1 virus. High mortality has been seen in young ostriches in some outbreaks; however, a virus isolated from one outbreak caused only green diarrhea in experimentally infected young birds. Domesticated waterfowl (e.g., ducks and geese) are often infected subclinically, although there may be mild signs such as sinusitis.

Wild birds infected with LPAI viruses usually have few or no obvious clinical signs, even during some epidemics among young birds at breeding colonies. However, subtle effects (e.g., decreased weight gain, behavioral effects or transient increases in body temperature) have been described in some cases.

The H9N2 viruses currently circulating among poultry in the Eastern Hemisphere appear to be relatively virulent, and can cause significant respiratory signs and malaise in chickens, including experimentally infected birds that are not co-infected with other pathogens. Both broilers and layers can be affected. Although quail are usually mildly affected by most other LPAI viruses, clinical signs were reported in some H9N2 outbreaks and experimentally infected birds. One H9N2 virus caused severe clinical signs in experimentally infected quail, and mild signs in jungle fowl, while house sparrows developed respiratory signs, and crows (Corvus splendens) had mild or no signs. The zoonotic H7N9 LPAI viruses in China have caused only mild or asymptomatic infections in poultry and experimentally infected birds including poultry, parakeets and most songbirds. One house sparrow became ill with lethargy and loose droppings and died during the experiment, and one zebra finch died without clinical signs, but it is possible that these deaths were not caused by the virus.

**HPAI viruses in birds**

HPAI viruses usually cause severe illness in chickens and turkeys, and few birds in infected flocks survive. Marked depression, decreased feed and water intake, and other systemic, respiratory and/or neurological signs are often seen, but no signs are pathognomonic, and sudden death can also occur. Commonly reported signs include coughing, sneezing, sinusitis, blood-tinged oral and nasal discharges, ecchymoses on the shanks and feet, edema and cyanosis of the unfeathered skin on the head, comb and wattle (and snood in turkeys), and diarrhea. Egg production drops or ceases, and depigmented, deformed and shell-less eggs may be produced. Because a virus can be defined as highly pathogenic based on its genetic composition alone, HPAI viruses may rarely be found in chicken or turkey flocks that have mild signs consistent with low pathogenic avian influenza.

HPAI virus infections can be asymptomatic, mild or severe in other birds, including gallinaceous birds other than chickens and turkeys. Non-specific clinical signs (e.g., anorexia, lethargy), neurological signs, diarrhea and sudden death have been reported in gallinaceous game birds, but milder or minimal signs were seen in some flocks. Domesticated waterfowl tend to be mildly affected, but respiratory signs (e.g., sinusitis), diarrhea, occasional cases with severe acute disease with neurological signs and high mortality rates, have been reported in sporadic deaths and rare outbreaks. Reported clinical signs in one H5N1 HPAI outbreak included neurological signs, greenish diarrhea and sudden death. Some pigeons that were experimentally infected with H5N1 viruses remained asymptomatic, while others became moderately to severely ill.

There is limited information about avian influenza viruses in ostriches, but HPAI viruses may not necessarily be more pathogenic than LPAI viruses in this species. The clinical signs tend to be mild in adult ostriches, and more severe in young birds less than 6 months of age, which can develop nonspecific signs (e.g., depression), dyspnea; green urine, diarrhea or hemorrhagic diarrhea, with increased mortality. Elevated mortality reported in some outbreaks in ostriches, pigeons and other relatively resistant birds might be caused by concurrent infections and other complications.

Studies in experimentally infected wild birds and observations in captive and wild birds suggest that some species can be severely affected by Asian lineage H5N1 HPAI viruses, while others may have much milder signs or shed viruses asymptptomatically. During one H5N1 outbreak at a wildlife rescue center, some birds died without preceding clinical signs, while others developed anorexia, extreme lethargy, dark green diarrhea, respiratory distress and/or neurological signs, with death often occurring within 1-2 days. Some species at the facility did not seem to be affected. Neurological signs, varying from mild to severe, were reported in a number of experimentally infected birds including some species of ducks, geese, gulls, house finches and budgerigars. Other experimentally infected birds, such as zebra finches, had high mortality rates, but only nonspecific signs of depression and anorexia. Starlings and some species of ducks were mildly affected or unaffected, while house sparrows developed severe clinical signs in one study, and remained asymptomatic in another. Information about the effects of other HPAI viruses on wild birds is limited. Wild waterfowl seem to be resistant to clinical signs, but an H5N3 HPAI virus caused high mortality among South African terns in the 1960s. A wild skink naturally infected with an H7N1 HPAI virus was ill, and the same virus caused conjunctivitis, apathy and anorexia, with a high mortality rate, in captive canaries (Serinus canarius) that had been exposed to this bird.
Mammals infected with Asian lineage H5N1 viruses

Asian lineage H5N1 HPAI viruses have caused fatal disease, as well as milder illnesses or asymptomatic infections, in mammals. A few clinical cases have been described, at most, in each species. Both symptomatic and subclinical infections have been reported in felids. One cat had a fever, depression, dyspnea, convulsions and ataxia, and a few infected housecats were found dead.3,23,28 One of the latter cats was apparently well up to 24 hours before its death. Fatal illnesses with conjunctivitis and severe respiratory signs were described in experimentally infected cats.193,195,197,198 However, asymptomatic infections were reported in housecats in an animal shelter that had been accidentally exposed to a sick, H5N1-infected swan.264 Some captive tigers and leopards died with clinical signs of respiratory distress, serosanguineous nasal discharge, high fever and neurological signs.21,22,25,30 In another outbreak, captive lions, tigers, leopards and Asiatic golden cats were lethargic and had decreased appetites (without respiratory signs) for 5-7 days, but recovered.31

A dog that had eaten infected poultry developed a high fever, with panting and lethargy, and died the following day.29 However, serological and virological evidence of infection has also been found in stray dogs in China during routine surveillance.34 Most experimentally infected dogs remained asymptomatic or had relatively mild signs such as fever (which was transient in some studies), anorexia, conjunctivitis and/or diarrhea.33,197,198 More severe respiratory signs (cough, labored breathing), with one fatal infection, were reported only in dogs inoculated directly into the trachea.33 Experimental infections, as well as reports of infected herds, suggest that H5N1 HPAI virus-infected pigs usually remain asymptomatic or have only mild signs (e.g., mild respiratory disease and anorexia).36,35,189,198,362

Fever, respiratory and/or neurological signs, as well as sudden death have been reported in a handful of cases in other species.9,30,32 Serological evidence of infection has been found in donkeys and horses, and an H5N1 virus was isolated from one combined sample collected from 3 donkeys during a respiratory disease outbreak in Egypt.19,189 However, these animals responded well to antibiotics, suggesting that the illness may have been caused or exacerbated by bacterial pathogens. Fatal respiratory disease, and possibly diarrhea, was reported in H5N1 virus-infected raccoon dogs, while captive palm civets had neurological signs, with evidence of interstitial pneumonia, encephalitis and hepatitis at necropsy, and a wild stone marten was found with neurological signs.30,32

Mammals infected with other subtypes

Infections with influenza A viruses, apparently of avian origin, have been associated with outbreaks of pneumonia in seals.1,184,414,415 The clinical signs included weakness, incoordination, dyspnea and subcutaneous emphysema of the neck.30,271,414 A white or bloody nasal discharge was seen in some animals. Experimental infections with these viruses were milder or asymptomatic, suggesting that co-infections may have increased the severity of the illness.30 An influenza virus was also isolated from a diseased pilot whale, which had nonspecific signs including extreme emaciation, difficulty maneuvering and sloughing skin.414 Whether this virus was the cause of the disease or an incidental finding is uncertain.355 Other viruses were isolated from whales that had been hunted, and were not linked with illness.316

There are only a few reports of naturally acquired or experimental infections in other mammals, except in animal models for human disease (ferrets and mice). An H10N4 virus caused respiratory signs (sneezing, coughing, and nasal and ocular discharges) and elevated mortality in mink during an outbreak in Europe.1,30 Respiratory signs were seen in a dog infected with an H5N2 HPAI virus (which was closely related to H5N1 viruses), and this virus caused mild respiratory signs in experimentally infected dogs.163,209 One cat exposed to these dogs developed respiratory signs and conjunctivitis, but 4 other cats seroconverted without clinical signs.208 Coughing, sneezing and nasal discharge were reported in dogs inoculated with an H9N2 virus, and 13 H9N2 viruses were isolated from sick and healthy dogs in a study from China.170,217 Some of the sick dogs in the latter study had clinical signs that could be consistent with influenza virus infections, but other infected dogs had signs likely to be unrelated.170 Few or no clinical signs were seen in cats inoculated with an H7N7 HPAI virus isolated from a fatal human case, cats inoculated with several LPAI viruses from waterfowl, or raccoons experimentally infected with an H4N8 virus.236,237,242

No natural infections with the zoonotic H7N9 LPAI viruses in China have been reported, as of September 2014, and experimental inoculation of this virus resulted in fever alone in cynomolgus macaques and asymptomatic infections in miniature pigs.220

Post Mortem Lesions

Low pathogenic avian influenza in birds

Poultry infected with LPAI viruses may exhibit rhinitis, sinusitis, congestion and inflammation in the trachea, but lower respiratory tract lesions such as pneumonia usually occur only in birds with secondary bacterial infections.2,3 Lesions (e.g., hemorrhagic ovary, involuted and degenerated ova) may also be observed in the reproductive tract of laying hens, and the presence of yolk in the abdominal cavity can cause air sacculitis and peritonitis.2 A small number of birds may have signs of acute renal failure and visceral urate deposition.5

Highly pathogenic avian influenza in birds

The lesions in chickens and turkeys are highly variable and resemble those found in other systemic avian diseases.408,417 Classically, they include edema and cyanosis.
of the head, wattle and comb; excess fluid (which may be blood-stained) in the nares and oral cavity; edema and diffuse subcutaneous hemorrhages on the feet and shanks; and petechiae on the viscera and sometimes in the muscles. There may also be other abnormalities, including hemorrhages and/or congestion in various internal organs including the lungs, as well as severe airsacculitis and peritonitis (caused by yolk from ruptured ova). However, the gross lesions in some outbreaks may not fit the classical pattern, and birds that die peracutely may have few or no lesions.

Variable lesions have also been reported in other gallinaceous birds. Necrotic lesions in the pancreas (multiple foci of parenchymal discoloration) are common in quail and partridges infected with some HPAI viruses. There may also be splenomegaly with parenchymal mottling, renal lesions, hemorrhages in internal organs and skeletal muscles, and pulmonary lesions (consolidation, edema, congestion and hemorrhages). However, some lesions seen in chickens and turkeys, such as cyanosis and hemorrhagic lesions in unfeathered skin, may not be as prominent in other gallinaceous birds. In ostriches infected with avian influenza viruses, the gross lesions are usually hepatitis and peritonitis, with other secondary lesions. Petechial hemorrhages, pancreatic lesions (e.g., multifocal hemorrhagic necrosis), pulmonary congestion and edema, and additional gross lesions have been reported in other species of birds infected with HPAI viruses.

**Avian H5N1 influenza viruses in mammals**

Asian lineage H5N1 HPAI viruses can cause systemic lesions as well as pulmonary lesions in some animals. Gross lesions reported in some cats and other felids included pulmonary consolidation and/or edema, pneumonia; hemorrhagic lesions in various internal organs; and in some cases, other lesions such as multifocal hepatic necrosis, hemorrhagic pancreatitis, or cerebral, renal and splenic congestion. Bloody nasal discharge, severe pulmonary congestion and edema, and congestion of the spleen, kidney and liver were reported in a naturally infected dog. Pulmonary lesions including interstitial pneumonia have been noted in some experimentally infected pigs, while others had mild to minimal gross lesions.

**Diagnostic Tests**

Avian influenza viruses can be detected in oropharyngeal, tracheal and/or cloacal swabs from live birds, with differing recovery rates from each site depending on the virus, species of bird and other factors. Very small (pediatric) swabs can be valuable in small birds, but feces can be substituted if cloacal samples are not practical (e.g., cannot be collected without harming the bird). Samples from internal organs (e.g., trachea, lungs, air sacs, intestine, spleen, kidney, brain, liver and heart) are also tested in dead birds suspected of having HPAI. Diagnostic tests should be validated for the species of bird, and some tests that are useful in chickens and turkeys may be less reliable in other avian species.

Virus isolation can be performed in all species, and can be useful for virus characterization. Avian influenza viruses are isolated in embryonated eggs, and can be identified as influenza A viruses with agar gel immunodiffusion (AGID), antigen-detection ELISAs or other immunoassays, or by a molecular test such as RT-PCR. They can be subtyped with specific antisera in hemagglutination and neuraminidase inhibition tests, by RT-PCR, or by sequence analysis of the viral HA and NA genes. Genetic tests to identify characteristic patterns in the HA (at its cleavage site) and/or virulence tests in young chickens are used to distinguish LPAI viruses from HPAI viruses.

RT-PCR assays can detect influenza viruses directly in clinical samples, and real-time RT-PCR is the diagnostic method of choice in many laboratories. Viral antigens can be detected with ELISAs including rapid tests. As of 2012, the World Organization for Animal Health (OIE) recommended that antigen detection tests be used to identify avian influenza only in flocks and not in individual birds.

Serology can be valuable for surveillance and demonstrating freedom from infection, but it is not very useful in diagnosing HPAI infections in highly susceptible birds, as they usually die before developing antibodies. Serological tests used in poultry include AGID, hemagglutination inhibition (HI) and ELISAs. AGID tests and ELISAs to detect conserved influenza virus proteins can recognize all avian influenza subtypes, but HI tests are subtype specific and may miss some infections. Cross-reactivity between influenza viruses can be an issue in serological tests. Tests that can distinguish infected from vaccinated birds (DIVA tests) should be used in surveillance when vaccination is part of a control program.

**Treatment**

There is no specific treatment for influenza virus infections in animals. Poultry flocks infected with HPAI viruses are depopulated (this is generally mandatory in HPAI-free countries), while the disposition of infected LPAI flocks may differ, depending on the specific virus and the country.

**Control**

**Disease reporting**

A quick response is vital for containing avian influenza outbreaks, and in some cases, for minimizing the risk of zoonotic transmission. In addition to national notification requirements, HPAI viruses and LPAI viruses that contain H5 or H7 must be reported to the OIE by member nations. Veterinarians who encounter or suspect a reportable disease should follow their country-specific guidelines for
informing the proper authorities (state or federal veterinary authorities in the U.S. for diseases in animals). Unusual mortality among wild birds should also be reported (e.g., to state, tribal or federal natural resource agencies in the U.S.)

Prevention
The risk of introducing a virus to poultry or other birds can be reduced by good biosecurity and hygiene, which includes preventing any contact with other domesticated or wild birds, mechanical vectors and fomites including water sources. All-in/ all-out flock management is helpful in poultry flocks, and birds should not be returned to the farm from live bird markets or other slaughter channels. To help prevent reassortment between human and avian influenza viruses, people are encouraged to avoid contact with birds while suffering flu symptoms.  

Avian influenza vaccines may include both inactivated whole virus vaccines and newer recombinant vectored vaccines. Most vaccines are produced for chickens, although they may be validated for use in turkeys, and their effectiveness can differ in other species. In addition to suppressing clinical signs, some vaccines are capable of increasing resistance to infection, and decreasing virus excretion and transmission. However, clinical protection is not necessarily correlated with reduced virus shedding, and some birds can become infected even in the best case scenario. Thus, vaccination can mask infections if good surveillance programs (e.g., regular flock testing, the use of DIVA tests, and/or sentinel birds) are not used simultaneously.  

In different countries, vaccines may be used routinely to protect poultry flocks, as an adjunct control measure during an outbreak, or to protect valuable species such as zoo birds from highly virulent viruses such as H5N1. Vaccination in the U.S. is restricted and requires the approval of the state veterinarian, and in the case of H5 and H7 vaccines, USDA approval.  

During outbreaks, HPAI viruses are normally eradicated by depopulation of infected flocks, combined with other measures such as movement controls, quarantines and perhaps vaccination. Insect and rodent control, disposal of contaminated material, and thorough cleaning and disinfection are also important.  

For mammals, prevention involves avoiding close contact with infected birds or their tissues. Keeping susceptible animals indoors may be helpful during outbreaks.

Morbidity and Mortality

Birds
Exposure to influenza viruses and shedding patterns among wild birds are complex and likely to reflect their exposure to different habitats, as well as gregariousness and other social factors, and pre-existing immunity. Reported infection rates with LPAI viruses range from <1% to more than 40%, and seroconversion rates from <1% to greater than 95%, with much higher rates in birds from aquatic environments than terrestrial species. Some studies have reported that infection rates are higher in young birds than adults (e.g., young egrets and herons at breeding colonies or young ducks). Currently, surveillance suggests that carriage of H5N1 HPAI viruses in wild bird populations without unusual mortality events is rare.  

The prevalence of influenza viruses in poultry differs between nations, but commercial poultry in developed countries are generally free of LPAI and HPAI viruses. Even in these regions, LPAI viruses may be present in backyard flocks, live poultry markets and similar sources. HPAI outbreaks are uncommon under ordinary conditions, while LPAI outbreaks tend to occur more often. However, the continued presence of Asian lineage H5N1 HPAI viruses in poultry elevates the risk of outbreaks throughout the world, and especially in the Eastern Hemisphere. These H5N1 viruses tend to re-emerge during colder seasons in endemic areas.  

Avian influenza differs in severity, depending on the species of bird as well as the virus. LPAI viruses usually cause mild illnesses or asymptomatic infections in birds, including chickens and ducks, but outbreaks can be more severe when there are concurrent infections or other exacerbating factors. Some recent H9N2 viruses appear to be more virulent than most other LPAI viruses, while HPAI viruses tend to be highly virulent. High mortality is occasionally seen in wild birds infected with either LPAI or HPAI viruses, although adult birds seem to be only mildly affected by both.  

HPAI viruses usually cause high and rapidly escalating mortality in chicken and turkey flocks, with cumulative morbidity and mortality rates that may approach 90-100%. Any survivors are usually in poor condition and do not begin laying again for several weeks. Morbidity and mortality rates can sometimes approach 100% in other domesticated and wild birds, but susceptibility can vary greatly, and certain species such as waterfowl tend not to be severely affected. Some Asian lineage H5N1 viruses cause severe illness even in waterfowl, and the introduction of these viruses may be heralded by unusual deaths among wild birds (e.g., swans in Europe and recently crows in Pakistan). Thousands of wild birds were killed in some outbreaks, such as one at Qinghai Lake, China in 2005.  

Mammals
Pigs seem to be infected fairly often by avian influenza viruses from birds, often with only minor consequences even when the virus belongs to the Asian lineage of H5N1 HPAI viruses. Low levels of exposure have been reported for H5N1, H9N2 and other...
subtypes in some areas, with seroprevalence to these viruses typically ranging from 〈1% to 5%, and virus detection rates of 〈1% to 7.5% in pigs during H5N1 outbreaks among poultry. Some studies reporting higher seroprevalence to H5N1 viruses examined pigs in poor neighborhoods where they are fed dead bird carcasses and other organic remains, and in one Egyptian study, 8 of 11 positive samples came from a single herd. 35

H5N1 HPAI virus infections reported in housecats and large zoo felids ranged from asymptomatic to fatal, while experimentally infected cats exhibited severe disease with high mortality. 22,25,26,30,31,164,193,195 No seropositive cats were found in parts of Austria and Germany where these viruses had been found in wild birds, but low titers were detected in 8% of 25 cats in Egypt, and 73% of 11 cats in an unpublished study from Thailand. 17,189,455

Several avian influenza viruses have been reported in dogs, although in some cases, there may be little information about the consequences of infection. One fatal H5N1 HPAI case was reported in a dog, but experimental infections were mild or symptomatic in this species, except when the inoculation method bypassed normal upper respiratory defense mechanisms. 29,33,197,198 Surveys reported antibodies to H5N1 viruses in 25% of dogs during outbreaks in Thailand, 4% of 25 dogs in Egypt (low titers), and 1% of stray dogs in live markets and on poultry farms in China, with virological confirmation of infection from 2 dogs in China by PCR. 17,34,189 H9N2 viruses have also been isolated from dogs, 170 and surveys in China tested farm dogs, stray dogs living near live poultry markets and rural farms, and pets for antibodies to these viruses. 17,34,170 These studies reported seroprevalence rates ranging from 〈5% (with evidence of infection in 0.4% of dogs by RT-PCR) to 20-45%. Unpublished work also found serological evidence of exposure to H10N8 viruses in few feral dogs living near poultry markets, but whether this virus can affect dogs is not known. 340

The effects of Asian lineage H5N1 HPAI viruses on equids are still uncertain, but some surveys from Egypt reported that approximately 25% of donkeys and horses were seropositive. 19,189 Fatal infections with these viruses have also been reported occasionally in other species such as raccoon dogs, palm civets and mink, but little more is known. 26,27,30,32 An outbreak caused by a avian H10N4 virus in 1984 affected 33 mink farms in Sweden, with a morbidity rate of nearly 100% and mortality rate of 3%. 130 The severity of influenza in mink is thought to be influenced by co-infections and other factors. 1,30,83,87,456,457

Infections in Humans

Infection Period

Most zoonotic infections caused by Asian lineage H5N1 HPAI viruses seem to become apparent within approximately 5 days, although the incubation period for some cases may be as long as 8 and possibly 17 days. 177,181 Estimates of the mean incubation period for the zoonotic H7N9 viruses have varied from 3 days (in one analysis of a large number of cases) to 5-6 days, with a range of 1-13 days. 331,358,359,458

Clinical Signs

Asian lineage H5N1 HPAI viruses

Most infections with Asian lineage H5N1 HPAI viruses have been severe. 12,92,275 The initial signs are often a high fever and upper respiratory signs resembling human seasonal influenza, but some patients may also have mucosal bleeding, or gastrointestinal signs such as diarrhea, vomiting and abdominal pain. 177,181,459 Respiratory signs are not always present at diagnosis; two patients from Vietnam had acute encephalitis without symptoms to indicate respiratory involvement. 460 Similarly, a patient from Thailand exhibited only fever and diarrhea. 460 Lower respiratory signs (e.g., chest pain, dyspnea, tachypnea) often develop soon after the onset of the illness. 177,181 Respiratory secretions and sputum are sometimes blood-tined. 177 Most patients deteriorate rapidly, and serious complications including heart failure, kidney disease, encephalitis and multiorgan dysfunction are common in the later stages. 177,181,459 Milder cases have been reported occasionally, particularly among children. 275,461

H9N2 LPAI viruses

Most illnesses caused by H9N2 viruses have been reported in children and infants. 92,275-281 These cases were usually mild and very similar to human influenza, with upper respiratory signs, fever, and in some cases, gastrointestinal signs (mainly vomiting and abdominal pain) and mild dehydration. 92,275-281 All of these patients, including a 3-month-old infant with acute lymphoblastic lymphoma, 281 made an uneventful recovery. Acute, influenza-like upper respiratory signs were also reported in two adults, a 35-year-old woman and a 75-year-old man. 277 Severe lower respiratory disease, which developed into respiratory failure, was seen in a 47-year-old woman, who had chronic graft vs. host disease and bronchiolitis obliterans after a bone marrow transplant, and was receiving immunosuppressive therapy. 281 She survived after treatment with antiviral drugs, antibiotics for pneumonia, and supportive care, but required long-term oxygen supplementation on discharge.

Zoonotic H7N9 LPAI viruses in China, 2013-2014

Most clinical cases caused by H7N9 viruses in China have been serious, to date 14,15,219,351,462,463. The most common symptoms were fever and coughing, but a significant number of patients also had dyspnea and/or hemoptysis, and severe pneumonia (frequently complicated by acute respiratory distress syndrome and multiorgan dysfunction) developed in most laboratory-confirmed
A minority of patients had diarrhea and vomiting, but nasal congestion and rhinorrhea were not common initial signs. A common sign which is with some other avian influenza viruses and encephalitis were uncommon. In most cases, patients deteriorated rapidly after the initial signs. Concurrent bacterial infections were identified in some patients, and may have contributed to the clinical picture. A few uncomplicated cases were characterized by mild upper respiratory signs or fever alone, especially in children. At least one asymptomatic infection has been reported in an adult.

**Other avian influenza viruses**

Mild illnesses, with conjunctivitis and/or upper respiratory signs, have been reported in a number of people infected with various H7 LPAI or HPAI viruses and an H10N7 virus. One H7N7 HPAI virus, which caused only mild illnesses in most people, resulted in fatal acute respiratory distress syndrome and other complications in one otherwise healthy person. His initial symptoms included a persistent high fever and headache, but no signs of respiratory disease. The virus isolated from this case had accumulated a significant number of mutations, while viruses from most other infected individuals had not, and it also caused severe illness in experimentally infected ferrets and mice. Severe illness (pneumonia) was reported in a person infected with an LPAI H7N2 virus; however, he had serious underlying medical conditions, including HIV infection and infection with *Mycobacterium avium* complex. This patient was hospitalized but recovered without antiviral treatment. A 20-year-old woman infected with an H6N1 virus in China developed a persistent high fever and cough, progressing to shortness of breath, with radiological evidence of lower respiratory tract disease.

She made an uneventful recovery after treatment with oseltamivir and antibiotics. Severe lower respiratory tract disease, progressing in some cases to multiple organ failure and septic shock, was reported in three people with H10N8 infections in China. Two cases were fatal, one in a 73-year-old patient who had underlying health conditions, and another in a 75-year-old. The third patient, who was 55 years of age, recovered after mechanical ventilation and treatment with various drugs including oseltamivir. The other two patients also received oseltamivir.

**Diagnostic Tests**

Avian influenza viruses may be detected in samples from the upper and/or lower respiratory tract, depending on the site of the infection. RT-PCR is usually the primary test for Asian lineage H5N1 HPAI viruses. RT-PCR assays have also been published for the H7N9 influenza viruses causing outbreaks in China. Virus isolation can be performed, but it is slower. Antiviral resistance can be evaluated with phenotypic tests or gene-based testing to detect molecular markers of resistance, but is available in a limited number of laboratories, and takes several days to perform. Testing for novel influenza viruses is generally performed by state, regional or national public health laboratories, and in some cases by reference laboratories capable of handling dangerous human pathogens such as H5N1 HPAI viruses. Likewise, the H7N9 LPAI viruses are often sensitive to oseltamivir, and all of the H7N9 isolates from humans have contained a mutation suggesting resistance to adamantanes.

**Treatment**

Treatment for avian influenza may vary, depending on the severity of the case. In addition to symptomatic treatment, it can include various drugs, including antibiotics to treat or prevent secondary bacterial pneumonia, and antivirals. Two groups of antiviral drugs – the adamantanes (amantadine, rimantadine), and neuraminidase inhibitors (zanamivir, oseltamivir, peramivir and laninamivir) – are effective against some influenza A viruses, but some of these drugs (peramivir and laninamivir) are not licensed in all countries. Antiviral drugs are most effective if they are started within the first 48 hours after the clinical signs begin, although they may also be used in severe or high risk cases first seen after this time. Oseltamivir appears to increase the chance of survival in patients infected with Asian lineage H5N1 and H7N9 viruses, particularly if it is given early. Side effects including gastrointestinal and CNS effects are possible, particularly with some drugs.

Antiviral resistance can develop rapidly in influenza viruses, and may even emerge during treatment. At present, Asian lineage H5N1 HPAI viruses are usually sensitive to oseltamivir, and they are often (though not always) resistant to adamantanes. Although resistance to zanamivir and oseltamivir has been reported, it is currently uncommon. Likewise, the H7N9 LPAI viruses are often sensitive to oseltamivir, and all of the H7N9 isolates from humans have contained a mutation suggesting resistance to adamantanes. Oseltamivir-resistant viruses of H7N9 viruses have also been
described.\textsuperscript{306,464} One recent study documented low levels of resistance to neuraminidase inhibitors among avian influenza viruses in wild birds.\textsuperscript{487}

**Prevention**

Protective measures for zoonotic avian influenza viruses include controlling the source of the virus (e.g., eradicating HPAI viruses, closing infected poultry markets); avoiding contact with sick animals, animals known to be infected, and their environments; employing good sanitation and hygiene (e.g., hand washing); and using personal protective equipment (PPE) where appropriate.\textsuperscript{12,179,332} While the recommended PPE can vary with the situation and risk of illness, it may include respiratory and eye protection such as respirators and goggles, as well as protective clothing including gloves.\textsuperscript{12,423,488} The hands should be washed with soap and water before eating, drinking, smoking, or rubbing the eyes.\textsuperscript{423}

Because HPAI viruses have been found in meat and/or eggs from several avian species,\textsuperscript{60,150,319-325,391,489-493} careful food handling practices are important when working with poultry or wild game bird products in endemic areas, and all poultry products should be completely cooked before eating.\textsuperscript{12,423,494} Sanitary precautions and cooking methods recommended to destroy *Salmonella* and other poultry pathogens in meat are sufficient to kill avian influenza viruses,\textsuperscript{12} and eggs should be cooked until the whites and yolks are both firm.\textsuperscript{12,423} Wild birds should be observed from a distance, as they may be infected with some viruses, and hunters should not handle or eat sick game.\textsuperscript{423} H5N1 vaccines for humans have been developed in the event of an epidemic, but are not in routine use.\textsuperscript{12,495}

More detailed recommendations for specific groups at risk of exposure (e.g., people who cull infected birds, field biologists, and hunters) have been published by some national agencies, including the CDC, the Department of the Interior and U.S. Geological Survey National Wildlife Health Center in the U.S.,\textsuperscript{12,423,488,496} and international agencies such as the World Health Organization. In some cases, recommendations may include antiviral prophylaxis (e.g., for people who cull birds infected with Asian lineage H5N1 HPAI viruses) and/or vaccination for human influenza to reduce the risk of reassortment between human and animal influenza viruses.\textsuperscript{12,37,460} People who become ill should inform their physician of any exposure to avian influenza viruses.

**Morbidity and Mortality**

**H5N1 avian influenza**

Between 1997 and September 2014, there were more than 650 laboratory-confirmed human infections with Asian lineage H5N1 viruses, which generally occurred as the result of close contact with poultry.\textsuperscript{13} Illnesses caused by H5N1 viruses are, overall, rare; however, these viruses have been found in poultry (including small backyard flocks) for over a decade, resulting in high levels of human exposure. Most patients were young and had no predisposing conditions.\textsuperscript{181} The case fatality rate for all laboratory confirmed cases reported to WHO has consistently been about 59-60% in the last few years.\textsuperscript{13,261} Likewise, a summary of confirmed, probable and suspected H5N1 cases documented worldwide between 2006 and 2010 found that 56% of these cases were fatal.\textsuperscript{497} However, the case fatality rate differs between countries and groups of patients.\textsuperscript{497,499,501} It is lower in young children than adults,\textsuperscript{497,501,502} and in patients with milder symptoms at the time of diagnosis.\textsuperscript{502} One study found that rhinorrhea was linked to improved survival, possibly because it was indicative of milder cases or upper respiratory disease.\textsuperscript{501} Conversely, delays in antiviral (oseltamivir) treatment were associated with a worse prognosis.\textsuperscript{501} The case fatality rate seems to be particularly low in Egypt, where 28% of confirmed, suspect and probable cases were fatal between 2006 and 2010, and the median age of patients was 6 years.\textsuperscript{397} Their young age, which tends to be associated with early diagnosis, as well as treatment-related factors and the virulence of the circulating viruses might be factors in the relatively high survival rate.\textsuperscript{497,501,502}

Antibodies to H5N1 viruses have been reported in some poultry-exposed populations that have no history of severe H5N1 disease, fueling speculation on the likelihood of asymptomatic or mild infections.\textsuperscript{189,284,285,288,297,503-505} Most studies have reported seroprevalence rates of 0% to 5%, with a few reporting higher levels, and a meta-analysis of studies published before 2012 suggests that the overall seroprevalence is approximately 1-2% or less.\textsuperscript{189,284,285,288,289,296,297,503-505} Factors such as cross-reactivity with human influenza viruses in serological assays, or poor seroconversion to some avian viruses, might influence estimates of exposure, and the true prevalence of mild cases is still uncertain and controversial. Rare, laboratory confirmed, asymptomatic or mild cases have also been recognized.\textsuperscript{575,461,506} Rapid treatment with antiviral drugs might have been a factor in some of these cases; however, one child had only upper respiratory signs and made an uncomplicated recovery after antibiotic treatment alone.\textsuperscript{461,497,501,502} Prospective studies from Nigeria and rural Thailand documented rare instances of seroconversion to H5 avian influenza viruses, but were unable to find virological evidence of any avian influenza viruses during influenza-like illnesses.\textsuperscript{283,385,287} The occurrence of milder cases would be expected to lower the case fatality rate. However, it is possible that some severe cases have also been missed or attributed to other diseases; thus, the net effect of any undiagnosed cases is uncertain.

**H7N9 avian influenza**

Approximately 450 clinical cases have been caused by LPAI H7N9 viruses in China, as of September 2014.\textsuperscript{14,15} They mainly occurred in two waves, the first consisting of approximately 130 cases between February and May 2013,
and the second from October 2013 to May 2014, with sporadic cases reported between the two outbreaks.\textsuperscript{14,15,219,220,222} Although the second wave has subsided, further cases can be expected.\textsuperscript{15} This H7N9 virus seems to circulate subclinically in poultry, and human illnesses have mainly been associated with live bird poultry markets, although the source of the virus was uncertain in some cases, and exposure to backyard poultry or poultry farms was an additional risk factor in rural patients.\textsuperscript{15,223,330,332,507,508} During the first wave, culling of live birds in wholesale markets, and closure of markets with cleaning and disinfection, were associated with declines in the number of human cases.\textsuperscript{332} However, many live markets were not closed, or re-opened after being closed for a short period.\textsuperscript{220}

Many of the clinical cases have occurred in older patients.\textsuperscript{462} During the first wave, 55% of the patients were older than 59 years.\textsuperscript{331} Elderly men were overrepresented in urban areas, particularly in locations where their traditional family roles result in increased exposure to retail live poultry, but men were not affected significantly more often than women in rural regions.\textsuperscript{331,509} Most reported cases in adults (including young and middle-aged adults) have been serious, while many cases in children were mild.\textsuperscript{15,219,223,351,458,462,463} Some cases may have been mitigated by prompt treatment with oseltamivir, but other mild cases occurred in people admitted to the hospital for observation alone, or were identified only after the person had recovered.\textsuperscript{219,458,463,466} The reported case fatality rate in hospitalized, laboratory confirmed patients was approximately 36% during both waves.\textsuperscript{15,219,223} and the risk of death among hospitalized patients increased significantly with age.\textsuperscript{219} Concurrent diseases or predisposing causes have been reported in a significant number of patients (e.g., 45% of cases in the first wave), although serious cases and fatalities also occurred in previously healthy individuals.\textsuperscript{219,223,307,331,351,358,458,462,510} Delayed treatment with antiviral drugs was also suggested as a possible factor in the high case fatality rate.\textsuperscript{458,465}

The likelihood of additional, undiagnosed mild or asymptomatic infections is still being assessed. In the majority of cases, there was no virological evidence of exposure among patient contacts who developed influenza-like signs. Some of the known mild cases were identified through national virological sampling of people with influenza-like illnesses.\textsuperscript{216,223,46} However, these samples are collected from people who visit primary care centers with influenza-like illnesses, and some cases could have been missed.\textsuperscript{463} Some serological studies found no H7N9 reactivity among poultry market workers, healthcare staff, patient contacts and other populations.\textsuperscript{220,357,359,511-513} However, one recent survey detected antibody titers to H7N9 viruses in 6% of poultry workers, and very low titers in 14%.\textsuperscript{514} Another study, which used a higher cutoff for a positive titer, found that 7% of poultry workers had antibodies to this virus in May 2013, while 14% were seropositive 7 months later.\textsuperscript{515} Among the participants sampled at both times, half had rising titers. In both studies, only 1% or less of the general population had antibodies to this virus, and these titers were low.\textsuperscript{514,515} Although cross-reactivity with other H7 viruses that may circulate in poultry is possible, these surveys suggest that mild or asymptomatic infections may have occurred among poultry workers.

### H9N2 avian influenza viruses

Clinical cases caused by H9N2 viruses have mainly been reported in children.\textsuperscript{12,92,168,275-280} Most cases, including an infection in an immunocompromised infant, have been mild, and were followed by uneventful recovery. Severe illness was reported in an adult with serious underlying medical conditions.\textsuperscript{281} Most serological studies have found antibodies to H9N2 viruses in <1% to 5% of poultry-exposed groups in endemic regions, with one report of 9% seroprevalence among agricultural workers in Bulgaria.\textsuperscript{168,283-286,288,289,292,294,516} In the latter study, titers were mainly associated with household exposure to poultry. A prospective study of adults with poultry exposure in rural Thailand reported rare instances of seroconversion, but the two people who seroconverted did not report being ill, and no avian influenza viruses were detected in other people who had influenza-like illnesses.\textsuperscript{283}

### Other avian influenza viruses

Most reported infections with H7 viruses other than the H7N9 virus in China have been mild in healthy people, whether they were caused by an LPAI or HPAI virus; however, one H7N7 HPAI virus caused a fatal illness in a healthy person, while affecting others only mildly.\textsuperscript{84,265,271} Mild signs were reported in poultry workers infected with an H10N7 virus in Australia.\textsuperscript{274} but H10N8 viruses caused fatal infections in two elderly patients in China and a serious illness in a 55-year-old.\textsuperscript{282} A young woman infected with an H6N1 virus in China had evidence of lower respiratory tract complications, but recovered with treatment.\textsuperscript{262,263} The possibility of other, unrecognized infections may be suggested by the occurrence of antibodies to various subtypes, generally at a low prevalence, in people who are exposed to poultry or waterfowl.\textsuperscript{168,275,283,285,290-298,517-519}

Susceptibility (and/or seroconversion) might differ between viruses: 3.8% of poultry workers seroconverted during an H7N3 LPAI outbreak in Italy in 2003, but no seropositive individuals were identified in serum samples collected during H7N1 epidemics from 1999-2002.\textsuperscript{518} Rare seroconversion to H6, H7 and H12 viruses was reported in prospective studies of adults with poultry exposure in Cambodia and rural Thailand, but no clinical cases were identified.\textsuperscript{283,298}
